Abstract

This project is used to research and determine the feasibility for developing a secure chat server using C# and industry standard technologies. Research will be made into various threats server and presented with and way to mitigate, various industry standard technologies and libraries used in secure development.

This project will also discuss the prototyping and implementation of such as system as well as the results into investigation of the success for the final developed project.

Finally, this report will provide a critical evaluation and conclusion; highlighting areas in which the final developed project succeeds as well as areas in which the project could require additional work. Ending with identifying potential future and improvements that could be made this this project in any additional developments.

1 Introduction

1.1 Aim

This project aims to research and determine the feasibility of creating a secure chat server using the C# .Net framework that provides both a secure and functional experience; evaluating the feasibility of this both by the compliance to researched industry-standard security features and by the responses given by users on their experiences of using this project.

1.2 Objectives

1. To research various threats that a chat server and other servers face daily to gain a complete understanding of the various methods and attack vectors that a malicious actor may take to breach server security.
2. To research encryption methodologies used in the industry for message transmission and user data storage, this research will allow me to implement features to better secure data that is being sent to, sent from, and saved on the server.
3. To research pre-existing security technologies, protocols, and libraries that are either standard practice in the industry or are commonly used in the industry. Doing this research will allow me to ensure that the final project better lies with what is standard, and to ensure that I am using libraries that will better help the overall security.
4. To design and implement the researched security features, practices, and protocols into a secure chat server using C#. The server will need to be able to securely protect against common attack vectors researched and provide an easy to use client for message transmission and retrieval.
5. To test and evaluate the final solution of this project. After the server and clients have been finalised testing will be required to be undertaken to determine the success of the project. Evaluation of this testing and the overall project will be completed.

1.3 Project Delivery

1.3.1 Project planning

This project has 3 distinct and defined milestone deadlines, each requiring specific work to be accomplished by their respective deadline. These milestone intervals are designed to ensure feedback can be given and corrections can be made at appropriate points to keep the project workflow as uninterrupted as possible. Alongside milestone deadline requirements, weekly meetings with the project supervisor will be conducted to ensure that intermediate deadlines and project transparency can be retained; these meetings will be designed to ensure issues can be raised and addressed in a frequent and timely manner. The deadlines required to reach the milestone deadline are as follows:

TOPIC	DATE
MILESTONE ONE	26 th November 2021
MILESTONE TWO	11 th February 2022
MILESTONE THREE	6 th May 2022

1.3.1.1 Milestone one

For the milestone one deadline, the expectation is that all aims and objectives will be completed, background research is expected to be complete, and the beginning of feature prototyping is expected to have started. Write-ups for milestone one are expected to be rough drafts that will be expanded and finalised after the feedback in milestone 2. The Gantt chart for milestone one is as follows:

Figure 1 - Milestone one Gantt Chart

1.3.1.2 Milestone two

Milestone two will focus on finishing the development of prototype technologies and testing the performance of the prototypes; these prototypes will be written up and compiled into this report. Feedback will be received from milestone one submission, any recommended alternations made in the feedback will be appropriately made. Finally, the first implementations for the final product will be made in milestone two, these implementations will be written about before the milestone two submission. The Gantt chart for milestone two is as follows:

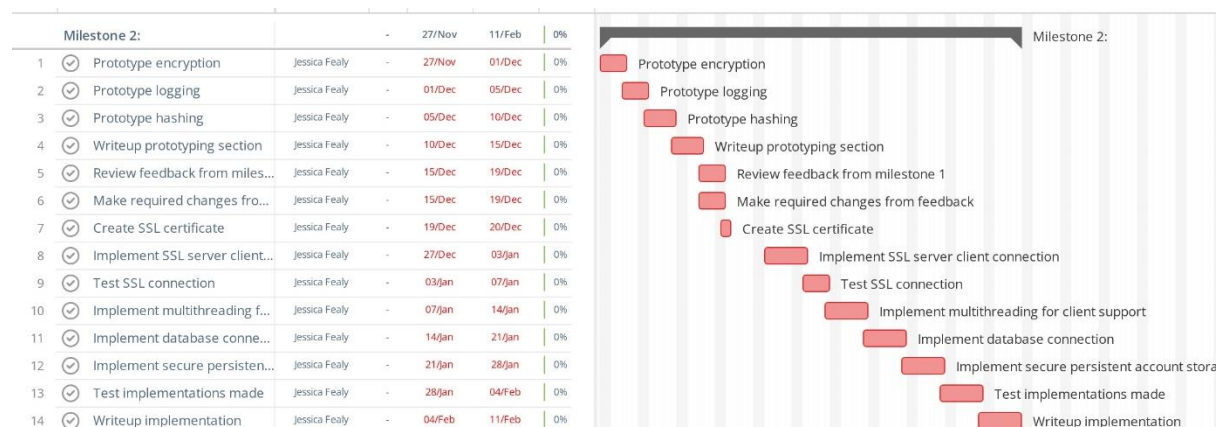

Figure 2- Milestone two Gantt Chart

1.3.1.3 Milestone three

Milestone three is arguably the most important period, this is where all work is completed and finalised for submission. During this milestone project code implementation is to be completed, tested, and written up. Then all user testing and critical analysis of the project's success are required with mentions of potential improvements that could be made to the project with future development and finally, conclude the project. The Gantt chart for milestone three is as follows:

Figure 3 - Milestone three Gantt chart

1.3.2 Project deliverables

Below is the required and desired outcome expected to be delivered by the completion of this project. These will be used to help evaluate the overall success of this project:

1.3.2 Required Outcome

- Encryption research.
- Research into secure security, protocol, and libraries.
- Research into security threats.
- At least one chat channel per server instance.
- Persistent user login data.
- Encrypted messages between client and server.
- Easy to use client interface.
- Implementation of other researched security features.
- Implement a logging system.
- Server able to manage multiple clients simultaneously.
- Local admin server login.

1.3.3 Desired Outcome

- Multiple chat channels on the same server instance.
- Remote admin server login.
- Private client communication (one-on-one).
- Data is stored securely in an external database.
- Client messages are stored locally securely.

2 Background Research

2.1 Actors, attack vectors, and mitigation

In terms of server security, a server is under threat by 3 main categories, human, nature, and technology (Jouini, Rabai and Aissa, 2014), in terms of this project only securing against the human and technological threats will be focused on, however, with a larger-scale solution nature threat would require more consideration.

This project will primarily focus on mitigating the following vulnerabilities:

- Account hijacking – this is where a malicious actor gains unauthorised access to an authorised user account. This attack may occur against general users, or more seriously admin privileged users. There are many ways in which an attacker may gain access to a user's account, this is primarily done via phishing or brute force attempts (Bamiah and Brohi, 2011). The way to mitigate against this form of attack is by ensuring users are aware of phishing attacks so they're better prepared for them and to ensure passwords are held to a standard to increase the time to brute force an attack.
- Man-in-the-middle (MITM) attacks – these attacks are caused when a malicious actor sits between the client and the server connection stream, this allows the actor to monitor, read, and interfere with messages sent between client and server (Swinhoe, D., 2021). A primary method to mitigate against MITM attacks is to set up a secure socket layer (SSL) between the server and the client (Irwin, 2021), this method ensures that both client and server can verify the message comes from the genuine sender.

2.2 Encryption

2.2.1 Different models of encryption

All encryption methods can be defined as either symmetric or asymmetric (Information Commissioners Office, n.d.), each category will give benefits and disadvantages depending on its use cases.

Symmetric cryptography is the method of using the same encryption key for both encryption and decryptions (Smirnof and Turner, 2019). Symmetric can be operated in two different modes, these are known as block cyphers and stream cyphers. Block cyphers segments all data (plain text) into static size blocks, these blocks have encryption applied to them. Stream cyphers segment the data into separate bits, each bit then has the encryption applied (Panhwar, 2019). Symmetric encryption has a potentially fatal flaw, regarding how the key is shared. This form of encryption has benefits over asymmetric methods by requiring less computation time for encryption and decryption, resulting in faster message transfer.

Asymmetric cryptography (also known as public-key cryptography) is an encryption methodology that uses 2 related keys for data encryption and data decryption. These 2 keys are known as the private and public keys, the public key can be shared on the open internet as plain data – this key is used exclusively for data encryption. The private key is required to be kept secret and is responsible for data decryption. Asymmetric cryptography is a much more secure encryption process compared to symmetric options, while with this security comes the downside of the heavy computation time required to encrypt or decrypt data. However, due to the nature that asymmetric public key can be freely shared and used by third parties for data encryption, there are no concerns with the secure distribution of keys as there is with symmetric variants (Simmons, 1979).

The speed advantages afforded to symmetric cryptography over asymmetric means while remaining a relatively high degree of security means that symmetric is the preferred method for bulk message encryption and decryption. Additionally, the primary flaw in symmetric cryptography being the ability to securely distribute their encryption keys can be answered by firstly using asymmetric cryptography. This can be done by machine A distributing their public asymmetric key, machine B encrypting their symmetric key using the public key from machine A and then distributing the asymmetrically encrypted message containing the

symmetric key. Machine A can then decrypt the received message from machine B using the asymmetric private key, this decryption process will result in machine A having access to machine B's symmetric key. In this example, the symmetric key has been securely transmitted to the desired location with only the person holding the private key with the ability to decipher the message (Anton, 2019).

2.2.2 RSA and AES

2.2.2.1 RSA Cryptography

Rivest-Shamir-Adleman (RSA) is an asymmetric encryption method that uses a key pair of a public and private key that is used for the encryption and decryption of data. A public key is used for data encryption; this key can be transferred over the internet as plain text with no security vulnerabilities arising. An RSA private key contains the information required to decrypt data; it is not considered secure to transfer an RSA private key in plain text over the internet. The process for the generation of an RSA key is as follows (Singh and Supriya, 2013):

1. RSA Modulus (n): the modulus is created from the multiplication of 2 large prime numbers with these prime numbers being labelled as q and p respectively. When multiplying prime numbers, the resultant value can only be factorised back into the original prime numbers, for smaller numbers a computer can relatively efficiently factorise to find q and p , however, when larger prime numbers are used (+1024-bit prime numbers) this time to factorise too considerably longer.
2. RSA Derived number (e): This number is derived from the prime numbers used for the calculation of the modulus and uses the equation $(p - 1)(q - 1)$.
3. RSA Private key generation (d): This is the private key secret exponent and is calculated by using the Extended Euclidean algorithm which is stated as $d = e - 1 \bmod n$ (Zhou and Tang, 2011).
4. RSA Public key generation: The public key is derived from both the modulus and the derived number.

2.2.2.2 AES Cryptography

A common industry standard for symmetric encryption is known as the Advanced Encryption Standard (AES); where RSA cryptographic will use 2 keys either encryption or decryption, AES will use the same key and initialisation vector (IV) for both these processes. The IV within the AES is generated as a pseudo-random number and is used to ensure that the data is being encrypted/decrypted the same number of times, this security feature is to ensure that the same encrypted text containing the same data do not generate the same cypher text (Domingus, 2020). This means like all symmetric encryption both parties are required to know the key and IV to be able to understand messages sent between the pair, this raises security concerns about how to safely communicate these keys between the parties involved.

The AES cryptographic process follows 3 primary steps each with its sub-phases, these being (Heron, 2009):

- The initial round
 - During the initial round, the XOR operation is performed between the plain text and the key.
- The intermediate round – this stage has 4 sub-phases that are performed
 - Substitution byte
 - Shift row

- Mix column
- Add round key

This step is repeated based on the key size of the AES key

- The final round
 - The final step does one last iteration of substitution byte, shift row, and adds round key phases in the intermediate round.

2.3 Other security features

2.3.1 SSL / TLS

SSL (Secure Socket Layer) / TLS (Transport Layer Socket) is widely used in the industry for secure communication across the internet, this protocol provides both the client and the server security, integrity, and authentication for all messages sent between them (SSL Support Team, 2021). For the process of connecting SSL between a client and a server the client will begin by connecting to the server sending an initial connection message along with a list of cypher suites that are supported by the client, the server will respond to this message with an initial connection message, a selected cypher suite and an X.509 Certificate (Adeenze-Kangah, 2019). An X.509 certificate is a digital certificate that can give a client trust in ensuring a server's authenticity, an X.509 certificate will contain the server's public encryption key and will contain the identity of the server. Using SSL and an X.509 certificate is a way to mitigate man-in-the-middle attacks and gives the client certainty in the connection to the correct server.

This certificate can be generated in two main ways by using a Certificate Authority (CA) or by self-signing a certificate. Certificate authorities are the industry-standard method to create X.509 certificates and are seen as the only secure way of doing so, this is because by using a certificate authority there is a trusted third party verifying the identity of the server. Where self-signing is not recommended to be used as there is not a third party verifying the authenticity of the certificate. Self-signing is only recommended to be used in testing environments or on private networks (Sectigo, 2021). This project will be utilising self-sign X.509 certificates to initialise an SSL connection.

2.3.2 Authentication

A major aspect of this project is allowing for the infrastructure for persistent user and admin login credentials. While there are libraries and third parties' solutions to managing this problem, an individual solution will be created for this project. The authentication system will function in a fashion where the server never has access to the unencrypted password; to do this the server stores a username, an account salt, and a secure hash of the salted user password. When a client attempted to log into the chat server, they send their unique account name or code to the server, this is looked up in the server's database with the server replying with a generated session salt and the account salt. The client will salt the user password with the account salt and hash this, then again salt the password with the session salt and hash this again, and the resultant is transmitted back to the server. The server will finally salt the received encrypted password with the session salt and hash this, then compared this final string with the stored salted password. Return a message to the client allowing or denying access to the server.

2.3.3 Hashing

While the most secure systems will implement practices to ensure difficulty for a malicious actor to breach any databases where confidential information is being stored, an assumption must be made that any malicious actor has unrestricted access to all systems and databases. With this assumption made security decisions must be made to ensure that even with access to the user databases they can retrieve no data that is critical to user account integrity.

For the protection of confidential data (in this case account passwords) it is common practice to implement hashing for the storage of persistent data (National Cyber Security Centre, 2018). Hashes are the result caused by using hash functions, these are one-way cryptographic algorithms that convert plain text into a hash value; these functions need to be deterministic meaning with the same input the same output is provided. Many different hash functions exist and are often applied in the industry all having their advantages and disadvantages, the primary functions that will be compared in this report are the Secure Hash Algorithm 256 (SHA-256) and the Password-Based Key Derivation Function 2 (PBKDF2).

Going from plain text to hash value alone can result in some critical security vulnerabilities, a commonly used attack on hash values is called a rainbow table attack. In essence, a rainbow table attack is a dictionary attack but optimised for hash values (Arias, 2019); by having commonly used passwords translated into hash values using common hashing algorithms, attacks can compare the rainbow table hash values to the server stored hash value to find any matching entries (Beyond Identity, n.d.) - If this process finds any matching entry, then the malicious actor has gained access to that account. Due to the efficiency that the rainbow table can compromise password authentication, it is now common practice to incorporate a salt with the original value and then hash the salted password (salt is a piece of randomly generated data that is near impossible to guess) (Arias, 2021). The inclusion of the salt makes rainbow attacks near impossible, meaning that attacks must rely purely on brute force attacks to breach security (LookingGlass, n.d.).

The two-hashing function mentioned SHA-256 and PBKDF2 each have their advantages and disadvantages; however, the American National Institute of Standards and Technology (NIST) now recommends that all passwords be stored using a key-based hashing function such as PBKDF2 (NIST, 2017). In general use of SHA-256 promotes a faster hashing algorithm for more efficient operations whereas PBKDF2 is designed to be slower and computationally difficult to generate hashes; for password security, a hashing algorithm ideally should be slow, this is to increase the time it takes for a malicious actor to attempt to breach password security (Dharmadasa, 2017). For this reason, this program will be utilising a key-based hashing algorithm such as PBKDF2 to have passwords for persistent storage.

2.3.4 Input Validation

An attack vector for a malicious actor can be any text entry fields available for user use, special concern for this attack vector must be taken into consideration due to the use of a database. A system lacking any form of input validation lays the risk of code injection, the biggest risk for this application is the potential for SQL injection. This form of code injection is where a malicious actor will attempt to enter SQL code to manipulate the back-end database, to protect against this form of attack all user inputs must be sanitised and validated to ensure that no entry can manipulate the database (William *et al*, 2006).

In recent months the improper implementation of input validation caused one of the worst exploits in recent years, this vulnerability was caused by the API Log4j. Log4j is used by many Java applications used software to log events that happen within the system, this allowed the developers to better track any issues that would occur, CISA (Cybersecurity and Infrastructure Security Agency) officials stated that “potentially millions of devices are likely to be affected” (ABCNews, 2021). The vulnerability inside Log4j allowed for malicious actors to inject code within any system that used this logging software, this could mean that personal data could be stolen from databases and systems could have malicious software uploaded to them allowing the malicious actors to have a backdoor into that system (NCSC, 2022).

Another important factor that must be considered with any inputs is non-malicious user inputs, while most users will not intentionally attempt to cause malicious harm to the computer system human error must be taken into consideration. When enforcing a password policy any user given a password when registering must be checked against this policy to ensure adherence. Additional when expecting data in certain formats such as emails, where you are expecting the usage of the ‘@’ character followed by an email service provider and then a domain. Emails entered must be validated against a criterion to ensure that emails entered are in the correct format, while the system cannot check whether the email is correct upon entry, the system can at least check whether the email address entered is within the correct formatting.

2.4 Libraries and other software

2.4.1 Development tools

The development of this project will occur using the Windows 10 operating system and Visual Studios Community Edition 2019 for the integrated development environment. The server will be using .Net Framework version 4.7.2, and the client created with .Net Framework 4.8 using Window Forms as the graphical user interface tool. These frameworks are specified for the Windows operating system and are unable to allow cross-compatibility with Linux or Mac OS systems (Microsoft, 2022).

2.4.2 Databases

Databases will be heavily integrated into the development of this project; they will provide a vital role in the security of login credentials and general logged data. The intention for this project is to have no sensitive information permanently stored on the computer that is hosting the server, doing so poses a risk of that data being stolen; instead, all sensitive data will be stored externally on a third-party server to help mitigate any risks. The chosen third party to host his database will be MongoDB, MongoDB provides a service that can be easily integrated with object-oriented programs, and uses a JSON message format, the same which will be used for message communications between the server and clients (MongoDB, n.d).

2.4.3 Logging tools

In software development logging provide a critical service (TowardsDataScience, 2020); this is by keeping a record of all activities taken place on a system, which can track any errors, security issues, or general information. Such logging information can be vital when trying to pinpoint any issues or to find any security flaws. This system will utilise try and catch blocks around any areas of critical code that can fail, such examples can be data type conversions and input validations, if these areas of code fail the catch block will catch the exceptions and a log will be generated providing a time stamp, location of the error, and the error is thrown.

Additional log entries will be created around all login attempts (admin and users) and when any new accounts are added, these logs will be used to track the security of the programs and will allow the admins to view where a brute force attack has taken place.

Logging for this program will be handled by external logging libraries, the libraries being considered are Log4Net (Watson, 2019) and NLog (NLog, n.d). A few primary differences exist between Log4Net and NLog, primarily the set-up for each with the former usually be configured using XML with limited ability to be programmatically configured, whereas NLog can be easily configured programmatically. Each logging library offers a similar set of logging functions, allowing for logs to be made in a variety of severity levels and for logs to be made in multiple locations at once (Console and text files). Log4Net is the chosen logging library that is going to be used and implemented in this project, with the ability to perform thread-safe operations and write logs to various locations at once; while in this project the logged data will remain to console or a file future development may want to be able to send logging event to a database and Log4Net allows this via the appenders (Apache, n.d).

3 Prototyping

GitHub repo link: <https://github.com/JeCFE/Final-Year-Project>

3.1 Server

Early prototyping for this project consisted of creating an initial server that can communicate to several clients at the same time. When a client sends a message to the server the server would respond to that client with the message "Received ". This prototype was created to ensure that multiple clients can connect to the server, with the server broadcasting a message to only the client that initiated communication.

3.1.1 The Early Server

The server has a hard coded IP address and port number initialised to the hosting PC, in future iterations this will be adopted for the IP and port numbers to be assigned by an admin at run time for the server, this should also be adopted to allow the ability to save these settings. No multithreading has been used in this iteration with an infinite while loop being implemented to constantly listen to new clients connecting to the server, and in the same loop to listen and send messages to relevant clients.

3.1.2 The Early Client

The initial client, knowing that the server has consistent connection settings, would automatically connect to the client on run time. Unlike the server, the client has used multithreading to allow for listening to messages from the server, delegates have been used to communicate the messages received outside the separate thread and update the relevant label.

3.2 RSA encryption

Early developments using RSA encryption were to encrypt an entire message stream using different functions to simulate the communication streams between server and client. Numerous issues occurred during this stage of prototyping, primarily RSA's difficulty to encrypt long data streams. Further research committed into industry standard encryption methods concluded in the using RSA to encrypt an AES key for key sharing, then using AES encryption for all messages between client and server.

3.3 RSA and AES encryption

For the prototype, both an AES key and RSA key are generated, to simulate and validate the potential of encrypting an AES key using RSA on the server and communicating this to the client for the client to decrypt the AES key using RSA for all message communication. An AES key was both encrypted and decrypted using RSA before attempting to decrypt a message to ensure that is no loss in data or ability for encryption through this process.

```
var csp = new RSACryptoServiceProvider(2048);
var privKey = csp.ExportParameters(true);
var pubKey = csp.ExportParameters(false);

Console.WriteLine("INPUT MESSAGE");
string message = Console.ReadLine();
Aes aesKey = Aes.Create();
Console.WriteLine(System.Text.Encoding.Default.GetString(aesKey.Key));
byte[] encryptedAESKey = csp.Encrypt(aesKey.Key, RSAEncryptionPadding.Pkcs1);
byte[] encryptedAESIV = csp.Encrypt(aesKey.IV, RSAEncryptionPadding.Pkcs1);
string strEAesKey = System.Text.Encoding.Default.GetString(encryptedAESKey);
string strEAesIV = System.Text.Encoding.Default.GetString(encryptedAESIV);
Console.WriteLine(strEAesKey);
Console.WriteLine(strEAesIV);

byte[] decryptedAESKey = csp.Decrypt(encryptedAESKey, RSAEncryptionPadding.Pkcs1);
byte[] decryptedAESIV = csp.Decrypt(encryptedAESIV, RSAEncryptionPadding.Pkcs1);
string strDAesKey = System.Text.Encoding.Default.GetString(decryptedAESKey);
string strDAesIV = System.Text.Encoding.Default.GetString(decryptedAESIV);
Console.WriteLine(strDAesKey);
Console.WriteLine(strDAesIV);
byte[] encrypted = EncryptStringToBytes_Aes(message, aesKey.Key, aesKey.IV);

string plainText = DecryptStringFromBytes_Aes(encrypted, aesKey.Key, aesKey.IV);
Console.WriteLine(plainText);
```

Figure 4 - RSA AES Encryption Prototype

3.3 Secure Logging

A prototype logging system was created to test race conditions when a read request is performed to a file that is being actively written to by Log4Net. The tests performed had 10 threads committing 100000 logs to the same text files concurrently with user random log reads requests being committed, these tests showed that that was no there was no data loss in the logs when the user was reading from the file.

For these tests to happen a Log4Net logger was created in XML with the following statements:

```
<appender name="RollingFile" type="log4net.Appender.RollingFileAppender">
  <file value="logs/Log_" />
  <datePattern value="dd-MM-yyyy'.txt'"/>
  <appendToFile value="true" />
  <staticLogFileName value="false"/>
  <lockingModel type="log4net.Appender.FileAppender+InterProcessLock"/>
  <layout type="log4net.Layout.PatternLayout">
    <conversionPattern value="%date [%thread] %-5level %logger - %message%newline"/>
  </layout>
</appender>
```

Figure 5- Log4Net Rolling File XML Configurator Prototype

Where the XML file highlights the lockingModel using the type InterProcessLock, this line ensures that the logger has exclusive access to writing to the file for each write attempt, once the logger has finished writing the lock is released. While the write access to the file has been locked whenever the logger is writing to the file, the read access has been left unlocked this allows the program to read from the file whilst the logger continues to write. For the read access from the file the following code was implemented:

```
try
{
    using (FileStream fileStream = new FileStream(
        "..\\Debug\\logs\\Log_27-01-2022.txt",
        FileMode.Open,
        FileAccess.Read,
        FileShare.Write))
    {
        using (StreamReader streamReader = new StreamReader(fileStream))
        {
            log.Info("Begin");
            Console.WriteLine("-----");
            Console.WriteLine(streamReader.ReadToEnd());
            Console.WriteLine("-----");
            log.Info("End");
            streamReader.Close();
        }
        fileStream.Close();
    }
}
```

Figure 6 - Reading From Log4Net Log File Prototype

Using FileStream allows the files to be locked in limited use, this statement opens the file, set the read access to read-only and then allows the files to be continuously written to by the logging system. Through testing, there are no data loss or integrity issues when reading and writing to a file at the same time.

3.4 Hash Testing

For the final development of the chat server, all account passwords will be salted and hashed for both transmission and persistent storage of these passwords. The following code was

created to test and simulate the salting and hashing process that was later incorporated onto the final solution. This test code will attempt to follow the authentication process highlighted in section 2.3.2 Authentication of this report. The process of this code is to first generate 2 random salt values named as accountSalt and sessionSalt; The user is then asked to enter a string password, this password and accountSalt are then hashed using the function called Hasher, this function uses a PBKDF2 hashing function using 10000 iterations, the return hash value is return and called persistantFirstHash (in a real application this is the hash value that is stored to a database). This persistantFirstHash and sessionSalt then use the Hasher function again with the resultant being called persistantFinalHash (on the server this hash value will be the hash value used for authenticating user login). The next stage asks the user for the password again, this is to simulate the user logging into an account with these new hashes being used to authenticate the user. The new hashes go through the same stages as the persistent hashes, using the same hash values the plain text password is hashed once with the accountSalt and then the result is hashed again using the sessionSalt. In the application, the loginFinalhash will be transmitted to the server for comparison to the persistantFinalHash, in this test code a simple if statement is used to compare these two values. The code below shows the test code solution:

```

4 Implementation

The implementation of the completed C# secure chat server can be considered as the second iteration of development, each prototyped technology will be adopted and implemented into a seamless completed project. Each prototyped stage has been tested in a closed system with no interaction with other sections of prototyped technology. With each implemented prototype into the second iteration of development, further testing will be completed to ensure that the adoptions have been implemented correctly before additional sections of prototypes are incorporated. The development will between server and client be done concurrently due to the nature of testing messaging and encryption infrastructure.

4.1 JSON messaging system

During the early stages of development, an issue was raised where not all messages sent between server and client were intended to be distributed to all connected clients and were instead intended for direct communication of data or instructions between server and client. Such types of communication include a need for a recognised encryption handshake, login request, registration request, and general messaging. Both server and client contain classes for the communication types mentioned before, these will be used serialising and deserialising JSON data into a string. Another master JSON class exists called Message. This class contains 2 string variables, one called id and the other called message; id is used to refer to the which communication type is being sent, such as id 0 will refer to the message containing the information required for the encryption handshake. The message variable is used to store the JSON string from the serialisation from one of the other classes, knowing that id 0 means that message is for handshaking the message variable can be deserialised into the HandShakeMessage class seamlessly. This messaging system allows for future growth and additions when needed, with the only changes being required for a new addition is the addition of another class to handle the data for JSON serialisation and deserialization.

4.2 RSA and AES key exchange

Under common systems both server and client will already know the RSA keys used for encryption via the certification used during the SSL handshake, however, due to the nature of this certificate, nothing was signed by a certification authority the decision was made to create a custom secure handshaking protocol whilst still using the initialised SSL tunnel. The protocol required the server to generate a 2048-bit RSA key, this has been created and stored within an authentication class to separate RSA encryption from the ClientHandler class. The client would be responsible for the creation of their unique AES key and IV. Some issues arise from the implementation of the prototype RSA AES exchange to the chat server, this error existed when trying to convert the RSA public key into an XML string for transmission to the client, when the server attempted to decrypt messages sent from the client (when the client used to import the RSA key from XML) there was an issue with a mismatch of keys. This error was solved simply by not converting the RSA public key into an XML string and rather transmitting the raw byte data instead the lack of conversion back and forth being byte and string solved the errors being experienced. The general transmission used in the key exchange used the JSON messaging system and the HandShakeMessage. Upon a client connecting to the server, the server would send the client the RSA public key, the client would then encrypt their AES key and IV storing this data into the HandShakeMessage class, the client would also then encrypt a common word known between both client and server using AES. The server upon receiving the message from the client would decrypt the AES key and IV using the RSA private key and store the AES data inside the client handler class, the server would then decrypt the test message using the AES decryption, if the word matches what was expected the server will send the client confirmation, else the server would send the client noticed that the process had not worked.

4.2 Database and persistent data storage

The database integration was not prototyped due to the database provider MongoDB providing supporting material which instructions on how to connect a C# program to the database server. This project uses 2 separate tables for data storage, one named Accounts and is responsible for the storage of general user login details, this includes a name or nickname, an account salt, last logged in, and a hash value of the account password. The other

table used is called Admin, this table contains information pertinent to the login for admin users, this table includes admin id codes, last logged in, and hash values for the admin.

4.3 User login and account registration

For both the client and server all login attempts, and related communications are handled using the JSON messaging system using the LoginInformation class, for all registration and related communications the RegistrationInformation class is used. Descriptions of the stage ID codes used for each can be found under the appendix *9.3 Login and Registration System*.

A login process for a user will require the user to enter an email address and password, the client will then send the server the entered email address. This email address is looked up in the database to ensure that the email address has been previously registered, if there is an account matching the submitted email address then a random session salt is created by the server and all account details are downloaded, including account salt and hash value. The account salt, session salt, and a confirmation that an account is found are transmitted back to the client. On receipt of the client receiving this message from the server, the client will be proceed to salt the entered password using the account salt, the client will then salt and hash this value using the session salt. After the client has generated the hash value of the user's password this is then transmitted back to the server for comparison. Once the hashed password from the client has reached the server side, the server will then have the saved hash value with the session hash – this process ensures that both the saved hash and the client hash have all gone through the same process. Both the server-side hash value and the client hash value are compared, if these values are equal then the user had entered the correct password, else the client has entered the incorrect password; the result of this comparison is transmitted back to the client, either the client has access to the chat server, or they must go through all the stages of logging in again.

Where a user does not have an account or wishes to create a new account on the server, they will be required to enter a nickname, email address, and password, all this data will be transmitted to the server using the RegistrationInformation class in JSON format. The server will look up the email address provided by the client on the accounts database, if the email address already exists in the database the registration cannot continue and the user must enter a different email address, else the server will generate an account salt and transmit this back to the client. Upon receipt of the account salt, the client will salt and hash the entered password, the client will then proceed to create a JSON string from the RegistrationInformation containing the information of the hashed password, the email address, and the nickname – all this information will transmit back to the server. On the server side, these details will be deserialised and a new user account will be created on MongoDB.

4.4 SSL Connection

As was mentioned throughout the background research topic covering SSL / TLS server and client connections the method being used is a self-signed X509 certificate, this certificate has been created with the open-source technology of OpenSSL. The OpenSSL commands used for the generation of the SSL certificate can be seen below:

```

C:\WINDOWS\system32>openssl genrsa -aes256 -out server.key 4096
Enter PEM pass phrase:
Verifying - Enter PEM pass phrase:

C:\WINDOWS\system32>openssl req -new -key server.key -out server.csr
Enter pass phrase for server.key:
You are about to be asked to enter information that will be incorporated
into your certificate request.
What you are about to enter is what is called a Distinguished Name or a DN.
There are quite a few fields but you can leave some blank
For some fields there will be a default value,
If you enter '.', the field will be left blank.
-----
Country Name (2 letter code) [AU]:UK
State or Province Name (full name) [Some-State]:Wales
Locality Name (eg, city) []:Treforest
Organization Name (eg, company) [Internet Widgits Pty Ltd]:Student
Organizational Unit Name (eg, section) []:Student
Common Name (e.g. server FQDN or YOUR name) []:SecureChat
Email Address []:jessicaf091@outlook.com

Please enter the following 'extra' attributes
to be sent with your certificate request
A challenge password []:SecureChat
An optional company name []:Student

C:\WINDOWS\system32>openssl x509 -req -sha256 -days 365 -in server.csr -signkey server.key -out server.crt
Enter pass phrase for server.key:

```

Figure 12 - SSL Certification Console Generation

These commands first create an RSA 4096 bit key and save this under the server.key, then create a certificate signing request file; this file requires some information about the certificate authority due to this being a self-signed certificate the data entered to simply dummy data. The main important section of the second command is related to the challenge phrase, this is the password each client will need to echo back to the server when required to verify the SSL connection. Finally, the last command is related to the creation of the X509 certificate, this can then be installed on the machine that the server is being hosted. This certificate is only valid for a period of 365 days the expires, after a year a new certificate will be required; if the challenge phrase is changed the new time the certificate is generated then all clients will require an update to match the new phrase.

The server can only understand X509 certificates in the format of PFX, this requires a final command using OpenSSL to convert the generated .crt certificate to a .pfx certificate, the command required is as follows:

```

C:\WINDOWS\system32>openssl pkcs12 -export -out server.pfx -inkey server.key -in server.crt
Enter pass phrase for server.key:
Enter Export Password:
Verifying - Enter Export Password:

```

Figure 13 - Conversion From Certificate To PFX File

The created server.pfx file is then copied into the directory containing the server executable and then everything else is managed internally by both the server and client. Upon the admin creating a new server, the server class finds the stored pfx SSL certificate and saves this to an X509Certificate2 variable. Each time the server received a client connection a new ClientHandler object is initialised, within this object the SetupConn function is run to setup the SSL connection between the server and client; for this connection to be set up the ClientHandler is required to define a new SslStream object, this containing the client Network stream which allows the server to read and write data on the stream, the SslStream must then authenticate the SSL stream by passing the SSL certificate and security protocol to the client.

On the client-side, the client follows similar steps of setting up the SslStream with the Network Stream, where the requirements differ is that client is required to verify the SSL certificate, when using an official certificate this would require called to the Certificate Authority that signed the certificate to ensure validity, however with this being a self-signed certificate this step must just return true. This is a security flaw within the server connection as realistically a fraudulent certificate could be passed to the client and the client wouldn't attempt to verify the validity of the connection, however, for this circumstance, this isn't avoidable. Once the client has verified the validity of the SSL certificate, the challenge phrase of "SecureChat" is echoed back to the server, once the server accepts this then the stream is verified, and the SSL tunnel is established.

4.5 Hashing

The implementation of hashing in the final solution of this project follows the design choices made for both the salt generation and the PBKDF2 functions shown in the prototyping stages have been directly exported in the authorisation class in both the server and admin. Testing was performed in the prototyping stages for the validity of the hash values generated when using the same input stream; in a server application, this means that hash values generated by using the PBKDF2 function can be reliably recalculated when the original passwords and salt values are entered into the system. Client-side hashing is responsible for hashing the entered user password twice, once with the account salt and again with the session salt. As mentioned during the research and prototype stages, hashing using the session salt ensures that the server can be certain of the sender of the login request. The server will take the hashed password from the user file and hash this using the same session salt the client used; the comparison of these generated hash values is a key principle of the authorisation system. PBKDF2 hashing requires the definition of hashing iterations

The salt generation is also held within the authorisation class and generates a pseudo-random 128-byte value using the RNGCryptoServiceProvider available within the .Net framework, after generation this salt value is returned either packaged to communicate between server and client and/or used within the PBKDF2 function.

4.6 Multithreading

The core of this project rotates around the ability for multithreading programming, all key systems in this project require the use of multithreading. Server-side multithreading lives on 2 layers, the first instance being the server itself; when an admin logs in and starts an instance of the server, this instance lives on a separate thread besides the primary thread. This multithreading has allowed the ability for the server thread to manage all clients and server related managements, whereas the primary thread is where the admin has access to adjust various factors of the server, primarily regarding adding and removing users and admin details, as well as monitoring log data. The server thread can also spawn multiple threads itself; these threads are related to the TcpListener thread that is required to listen to and handle any new connections from client machines; when this thread detects a new connection from a client another thread is spawned, this thread is related to handling all client data and communication and is handled by creating a thread in an instance of ClientHandler. The final thread handled server-side is within the ClientHandler thread, this new thread is responsible for listening for messages from that individual client. These threads mean that there is a theoretically infinite number of clients that the server can manage, as each client will not interfere with each other directly, however practically the limit on the number of

clients is bound by the CPU performance and the dedicated RAM as each new thread will require greater resources.

Client-side development for this project is much more simplistic on the multithreading requirements, client-side only requires 2 threads to run in parallel – with the new thread being spawned to handle listening for messages from the server.

Using multithreading on any project imposes the risk of race conditions with the potential of multiple threads attempting to access shared resources concurrently, this can incur the risk of one thread changing the contents of a variable before the first thread has finished. This project only uses 2 shared pools, these being the logging data files (client and server) and the database provided by MongoDB.

Regarding the shared databased mutex locks have been implemented on functions calls on the server class to only allow one thread at a time to have access to the database. The primary risk for when 2 clients are attempting to register the same user details onto the database, without any mutex locks this can result in some unforeseen errors. Mutex locks on key areas of shared pools mean that only one thread can manage shared data and others are placed in a queue to wait their turn. Managing race condition runs into the issue of decreasing overall performance and deadlocks, these are managed by only allowing threads to access shared memory, when necessary (which in the case of this program is only when logging in or registering), with deadlocks being managed by having the mutex locks timeout after a sufficient period if they haven't been released.

4.7 Client Handler

The Client Handler class has the primary responsibility for handling communications between the server and client, upon connection to the server a new Client Handler instance is created and appended to a vector of Client Handlers. Upon initialisation of the Client Handler class a new thread is created that is used to setup SSL connection between server and client, to start a new thread dedicated to listening for messages from the unique socket assigned to each instance of this class, and the finally to begin the hand shaking process – The handshake process has already been detailed previously. Other responsibilities of each Client Handler instance include managing special communications such as login and registration requests, these protocols have been previously detailed as well as the JSON messaging system. Additionally, each Client Handler contains the initialisation for unique logging, this logging is used to log data when a client's connection is authorised, if any errors occur with encryption or decryptions or in the event where any errors are likely to occur.

Each Client Handler has the unique responsibility of encrypting and decrypting messages using that connected client's unique AES encryption data, the design decision to contain the encryption and decryption internally of Client Handler retains the time efficiency of multithreading. If the encryption and decryption were held internally of the Authenticator class then each time a ClientHandler received a message or prepares to dispatch a message a lock would be required on the Authenticator function pertaining to the relevant function, this would ultimately lead to severe computational times for message sending. Additionally, having the encryption and decryption held within the Authenticator class would require each client AES key to be shared internally of the server, this leads to unnecessary security risks. With each Client Handler running its thread, and the AES key information already being stored within the class it made logical sense to contain the encryption and decryption processes

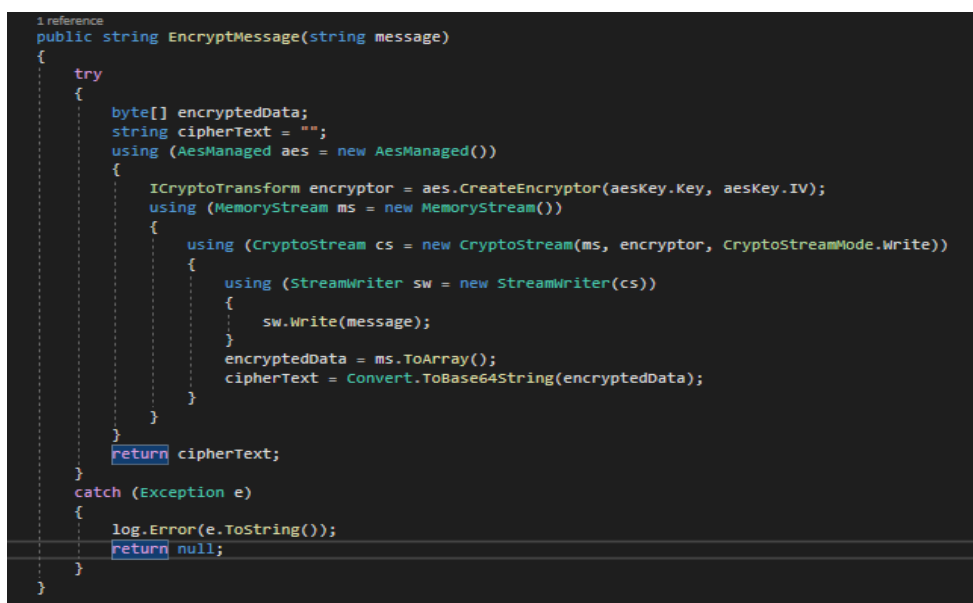

internal to the class. The actual AES encryption and decryption processes have already been detailed.

4.8 AES Encryption / Decryption

Both server and client sides have the same functions for handling the encryption and decryption of AES messages; on the server side, these functions are contained within the ClientHandler class, as this class already runs on a unique thread per client, so having AES management here will ensure that there is not a black log of AES management attempts when using the servers shared authorisation class. Whereas, for the client, AES management is contained within the authorisation class. Microsoft guides the implementation of AES encryption and decryption when using the .Net framework, this guidance has been followed with changes name to adopt the guidance to merge into this project's development.

4.8.1 Encryption

The entire encryption process is wrapped in a try-catch, this is to ensure any errors that might be thrown in the process are correctly logged and handled. The encryption process takes use of the C# using keyword, this ensures that the created object is destroyed when the program leaves the scope. The process requires 4 levels of objects existing with the using keyword, these are in order of AesManaged, MemoryStream, CryptoStream, and StreamWriter. Inside the AesManaged scope, an encryptor is created using the client's AES key and IV values; the CryptoStream is configured to use the MemoryStream, generated encryptor and is configured to Write mode. The StreamWriter is configured to read the CryptoStream, the StreamWriter then writes the entire CryptoStream is written to a byte [] variable. This variable is then converted to a base 64 string and finally returned; the returned string value is considered the cypher text. Any errors detected whilst encrypting will result in an error being caught and an error log is made.

A screenshot of a code editor showing a C# method named `EncryptMessage`. The method takes a `string message` as input and returns a `string`. It is wrapped in a try-catch block. Inside the try block, it declares a `byte[] encryptedData` and a `string cipherText`. It then uses a series of `using` statements to create and manage objects: `AesManaged` (named `aes`), `ICryptoTransform` (named `encryptor`), `MemoryStream` (named `ms`), `CryptoStream` (named `cs`), and `StreamWriter` (named `sw`). The `StreamWriter` writes the `message` to the `CryptoStream`, which is then converted to a byte array and finally to a base64 string. The catch block logs the error and returns `null`.

```
1 reference
public string EncryptMessage(string message)
{
    try
    {
        byte[] encryptedData;
        string cipherText = "";
        using (AesManaged aes = new AesManaged())
        {
            ICryptoTransform encryptor = aes.CreateEncryptor(aesKey.Key, aesKey.IV);
            using (MemoryStream ms = new MemoryStream())
            {
                using (CryptoStream cs = new CryptoStream(ms, encryptor, CryptoStreamMode.Write))
                {
                    using (StreamWriter sw = new StreamWriter(cs))
                    {
                        sw.Write(message);
                    }
                    encryptedData = ms.ToArray();
                    cipherText = Convert.ToBase64String(encryptedData);
                }
            }
        }
        return cipherText;
    }
    catch (Exception e)
    {
        log.Error(e.ToString());
        return null;
    }
}
```

Figure 14 - AES Encryption

4.8.2 Decryption

The AES decryption process is very similar to that of the encryption process with some notable differences, primarily the decryption process requires the input of a byte variable over a string variable. The levels of objects remain the same, with a decryptor being configured inside the

AesManagement scope using both the AES key and IV. The MemoryStream is configured using the provided cypher text, the CryptoStream is configured with the MemoryStream, decryptor, and configured to read mode. Finally, inside the StreamReader the stream is read to the end and saved into a string value. This value is now reverted to plain text and returned to the calling function. Like the encryptor, if an error is thrown in this function this is caught and an error log is made.

```

1 reference
public string DecryptMessage(string message)
{
    try
    {
        byte[] encryptedData = Convert.FromBase64String(message);
        string plainText = "";
        using (AesManaged aes = new AesManaged())
        {
            ICryptoTransform decryptor = aes.CreateDecryptor(aesKey.Key, aesKey.IV);
            using (MemoryStream ms = new MemoryStream(encryptedData))
            {
                using (CryptoStream cs = new CryptoStream(ms, decryptor, CryptoStreamMode.Read))
                {
                    using (StreamReader reader = new StreamReader(cs))
                    {
                        plainText = reader.ReadToEnd();
                    }
                }
            }
        }
        return plainText;
    }
    catch (Exception e)
    {
        log.Error(e.ToString());
        return message;
    }
}

```

Figure 15 - AES Decryption

4.9 Authentication Information

The authentication information class is used for the management of secure storage for sensitive information, this is both the admin and basic user admin details. This class contains 2 protected variables these being a list of items containing admin login information and the other being a list containing items containing user login information, the other variable held by this class is the initiation for the logger - the logger for this class is primarily used to log any errors detected when connecting to the database.

All information relating to admin and user login details is stored securely on a remote database being hosted by MongoDB, for the effective use of this information up the creation of the Authentication Information class a call is made to the remote database requesting all the information held relating to login details, these details are passed to the server using the BsonDocument data type. This data is extracted and converted to a string format that is saved into the class AccountData and AdminLoginAuthentication respectively, this is then appended to the protected list being stored by this class.

When a user or admin logs into the server their username or emails addresses are fed into this class where their details are checked against stored records, if a match is found then the stored account details are relayed back to the requesting origin point, if no match is found then a log is made reflecting this. When a user has passed checks relating to the authentication of a password the Authentication Information class is informed that a particular user has been permitted to log in and a Boolean flag is changed in the account details to ensure that each account can only have a single login at one time.

This class has the additional responsibility of the addition of new users and admin to the server, with most of the required registration information being confirmed with database lookups to ensure there are no duplicate email or username entries. Once confirmations that there are no pre-existing accounts with matching credentials exist then a connection to the database is made and a new entry is given with all the new accounts' relevant details, the account is also added to the live list hosted by the authorisation class so that user can log in straight away without a server restart being required.

4.10 Authentication

Both the server and client contain an authorisation class, with the server-side authorisation containing greater responsibility than the client-side. The client-side authorisation class is responsible for generating the client's AES details, this occurs when the constructor for the class is called. Additionally, this class is responsible for both the client encryption and decryption of both AES messages and handling the RSA handshake. Using both the functions `GetEncryptedAesKey` and `GetEncryptedAesIV` will take the public RSA key from the server and using the `RSACryptoServiceProvider` will encrypt both the AES key and IV using the provided RSA public key, this step is vital in the encryption handshake between client and server and will allow for future messages to be communicated via AES.

Within the server-side, the authorisation class hosted many more responsibilities, primarily used to act as a barrier between the main program and the authorisation information class. Hosting many functions classes between server/ClientHandler classes and the authorisation information class. Additionally, the server authorisation is responsible for RSA encryption and decryption, validating admin and user login attempts, hashing, salt generation, RSA key generation, and new account registration.

4.11 Logging

As was discussed in the background research and prototyping sections of this report the logging framework used for the final development is Log4Net, this framework boasts thread friendly file logging on various severity levels. During the prototyping stage, the XML configuration was constructed using guidance from Apache on how to configure a rolling appended logging file, the configuration made means that when each day rolls over a new log file is created and stored in the same folder with all other logs; this allows for the ability for admins to view logs with daily intervals rather than every logged event at one time. Each major class (a class that has actual function code) is initialised with a logger global variable, this variable is initialised with the filename of the class. This means any logs made using this variable will be written to the log file and will be associated with the class making the log. Additionally each log made will contain a time stamp, the thread the log was made on, the severity of the log, and the logged message. The configuration of the logger use can be found below:

```
<appender name="RollingFile" type="log4net.Appender.RollingFileAppender">
  <file value="logs/Log_" />
  <datePattern value="dd-MM-yyyy'.txt'" />
  <appendToFile value="true" />
  <staticLogFileName value="false" />
  <lockingModel type="log4net.Appender.FileAppender+InterProcessLock" />
  <layout type="log4net.Layout.PatternLayout">
    <conversionPattern value="%date [%thread] %-5level %logger - %message%newline" />
  </layout>
</appender>
```

Figure 16 - Log4Net Configuration Implementation

The class FileHandler is responsible for the management of reading data from and managing any data request from the log files, this includes updating the console with the most recent message and displaying specific logs request by the admin. With the log level being contained within squared brackets this allows the code to use the brackets as delimiters to be able to read what the severity of each log is. For instance, when an admin requests to view all INFO severity logs on a specific date, each log from that day will be analysed looking for the severity level, when a log has the INFO severity level this is saved to the string list; once the entire file has been completely read from all the logs with the required log severity is displayed onto the console. Admins are presented with options to read logs from any stored log folder and specifically look for ERROR, INFO, FATAL, or to view all logs from that day.

5 Results

5.1 Introduction

The success of this project can be weighed by a critical analysis of the final chat server produced in terms of functionality and performance. These tests are done either by direct analysis of the security features and testing edge cases to ensure they continue to follow expected results, and additional tests can be performed by gaining independent subjective opinions of peers for them to test, assess, and use the server in a way that was not originally intended to ensure that the server is well suiting to manage unexpected activities; these subjective opinions are gathered via a Microsoft forms document, querying the user to attempts various activities such as registering an account or asking the user to attempt to breach the server documenting how they did so. Finally, open-ended questions are asked to gain subjective opinions on topics such as the appearance of the chat client, and what features they would desire to see added or subtracted from any additional work.

5.2 Outcome of the project

This project carries the aim of researching and determining the feasibility of developing a secure chat server using C#, this has been completed by performing background research into computer security and industry standard security tools, processes, and protocols. Using this researched information prototypes were created for specific algorithms and classes; these were integrated into a complete C# secure chat server and client. Implemented technologies allow for the ability of secure persistent data storage, encrypted messages, secure registration, and login abilities, along with an easy to use chat interface.

5.3 Questionnaire

5.3.1 Questions 1 and 2

Throughout the testing phases, limited testing was done on computers external to the network in which the server hosting PC was located; this question was aimed to ensure that there were no issues with automatic connections to the server PC from external clients. 100% of respondents confirmed automatic connections succeeded. Additionally, if the clients were not able to automatically connect and an error message was provided the user is asked to provide the error code, this would allow for future debugging. In these questions, no users reported any errors.

1. Were you able to automatically connect to chat server via client? *

- ☐ Yes
☐ No

2. If you answered no to question one and if you received the error code what was this

5.3.2 Questions 3 and 4

This question is related to the ability of users to register an account from the client machine. All responding user has reported being successful in the creation of their client account, this is reflected in the MongoDB that shows the correct number of accounts saved with plaintext emails but hashed passwords. Another field is available for reporting any error codes if the client threw one; no reported issues were reported.

3. Were you able to create an account via the registration system *

5.3.3 Questions 5 and 6

These questions are relating to the ability of the end-user to be able to log into the account they created through the registration stage, the stages are very important as it verifies that the hashing process is correctly working and proves that the persistent user accounts can be continuously accessed with the correct password. 100% of users reported being able to successfully access the account they created through logging into the system, and no users reported any error codes relating to logging in failures.

5. Were you able to login to the account you created? *

5.3.4 Questions 7 and 8

Questions 7 and 8 are relating to the title bar of the client GUI, after a user has logged in the server is intended to dispatch non-sensitive personal information back to the client; one of these pieces of information is the account username assigned during the registration process. This question is intended to ensure that the user is logged into the correct account by assigning the client title bar as “You are logged in as *insert client username* “, if the username is that of what the user assigned then they are logged in to the correct account. 100% of respondents confirmed that the client received and used the correct username for the title bar of the client.

7. Did the title of the chat client GUI change that to match the username you have on record? *

☐ Yes

☐ No

8. If you answered no, what was the message shown

5.3.5 Questions 9 and 10

This question was optional for the user to answer and is related to the security of the client and/or server. This question asks the user if they had attempted to breach, penetrate, or break the server and/or client, if they were successful with their aim and if so, how the vulnerability was. 5 respondents reported either not attempting to breach or break the system or had not attempted to do so, while 2 other respondents had reported being successful at breaking the system in some way.

One respondent responded by stating they were able to crash both the server and all connected clients by attempting a denial of service attack, this is an attack where an attacker attempts to flood the server with traffic to interrupt normal server traffic (Cloudflare, n.d). The respondent stated they performed this attack by sending a blank message every millisecond until there was a crash.

The other respondent that reported a security vulnerability was related to decompiling the client executable, by using .Net decompiler they were able to backwards engineer the code which exposed security information (Dotnetsafer, 2021). The information exposed was the IP and port that's statically assigned, and the password required for SSL connections; while this information is not critical to the overall security, this information does allow for attacks to have an easier experience directly attacking the server. The respondent provided a screenshot of the backwards engineered project from JetBrains.

9. If attempted were you able to crash, breach, or in some other way able to penetrate either the encryption, hashing, or database?

☐ Yes

☐ No

10. If you answered yes, please explain how

Figure 26 - Responses from Questions Nine and Ten

1	Ben Harrison	Sent a message a millisecond and overloaded the server and crashed my local client.
2	anonymous	I used a .NET decompiler (specifically JetBrains dotPeek) to view the application's source code and retrieve the server's IP, port and SSL password. Using the IP and port, I then DDOS'd the server, causing a "Null Message" loop on the client end and requiring the client to be terminated with Task Manager.

Figure 27 - Detailed Responses from Questions Nine and Ten

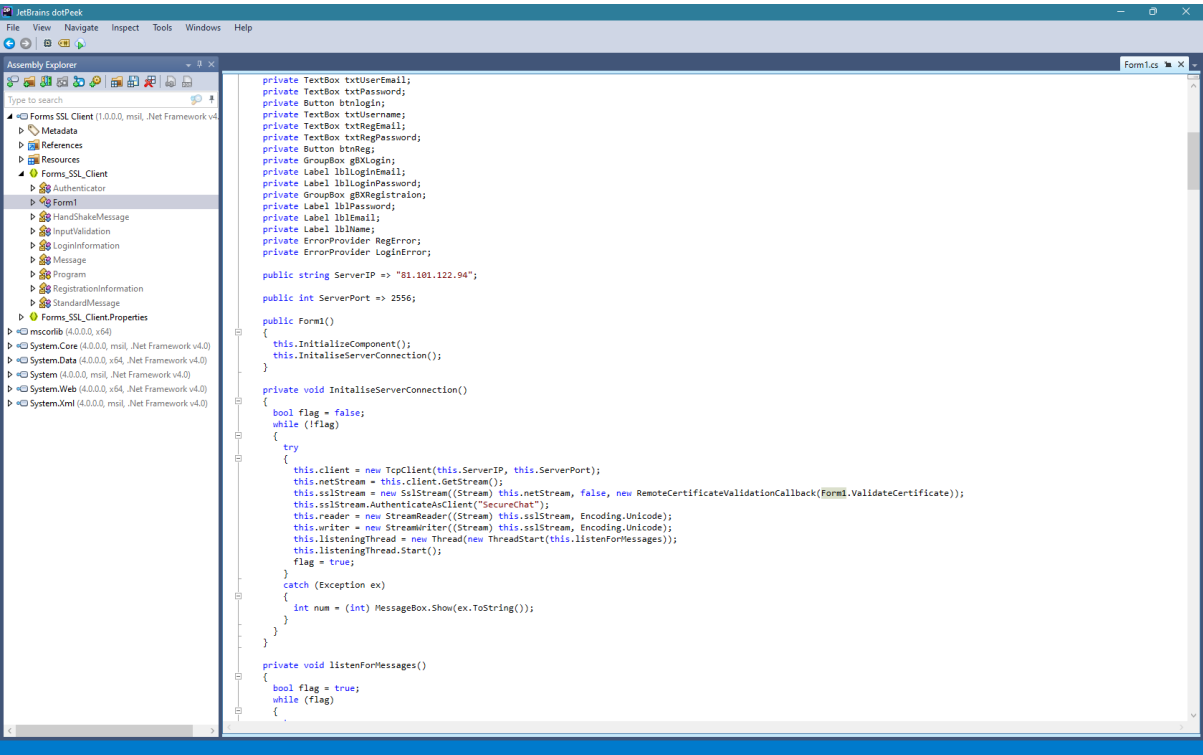

Figure 28 - Respondent Provided Evidence of Decompiling

5.3.6 Questions 11

This question related to the personal opinions of the respondent relating to the presentation of the client GUI, this project required a minimal and easy to use chat client that users found easy to navigate. All respondents responded stating they liked the minimalistic appearance with no cumbersome features that hinder operation.

11. What is your opinion of the GUI for the chat client? *

Enter your answer

Figure 29 - Question Eleven

1	Ben Harrison	Minimalistic, which is all you really need in a chat client. No additional features that cause over cumbersome GUI.
2	Michal Miroslaw Sakowski	nice and simple
3	anonymous	Simple and easy to use. Does the job
4	anonymous	It works as a chat server and I can talk to people.
5	anonymous	The GUI is functional, although the password fields should be asterix'd to hide input. The GUI's controls don't seem to be anchored, so they don't resize themselves when trying to resize the application (the application can also be resized to the point controls become hidden).
6	anonymous	The GUI has everything that is needed in order to have a chat client
7	anonymous	The GUI is very simple to use with it only having two buttons and a text window with a text box.

Figure 30 - Detailed Responses from Question Eleven

5.3.7 Question 12

This question relates to the subjective opinion of the user on features they wish they would see added and features they think are an issue. Most of the responses are relating to the anchoring of the GUI window, with that the moment resizing the window does not resize the other objects. Additionally, some were related to the quality of life improvements such as having the enter key send a message as well as using a send button and including timestamps of the messages sent.

12. What changes / features would you like to see added or removed from the chat server? *

Enter your answer

Figure 31 - Question Twelve

1	Ben Harrison	Remove the ability to resize the client window so the size is static
2	Michal Miroslaw Sakowski	enter should send message not add another line. List of participantce visible.
3	anonymous	The ability to submit a chat using the enter key. A little caption that explains who you are connected to, eg "you are now connected to Mark Pibble" etc.
4	anonymous	Resizable chatbox.
5	anonymous	Timestamp for messages.
6	anonymous	a private server would be a good addition
7	anonymous	removing the login details onces the user has created an account. being able to use the enter bar as well as the send button for sending a message

Figure 32 - Detailed Responses from Question Twelve

5.3.8 Question 13

Question 13 is the last question asked within this questionnaire and is used as a catch-all to ensure that any additional comments users want to state but were not provided suitable questions have a space to express their opinion. Most of these responses were briefly outlining that everything worked or was pleasant. However, one comment raised the issue of allowing the users to sign in using their username or email addresses to log in rather than only their email addresses.

13. Any additional comments?

Enter your answer

Figure 33 - Question Thirteen

1	Michal Miroslaw Sakowski	no it was best 5 minutes of my day: lovely people out there
2	anonymous	Allowing the use of Username/ email to log in rather than purely email.
3	anonymous	Lightweight and quick to set up.
4	anonymous	everything worked as intended

Figure 34 - Question Thirteen Detailed Responses

5.3.9 Questionnaire conclusion

This questionnaire and responses provided an essential insight into the opinion of the userbase the chat server is intended for, as well shown some security vulnerabilities that will be required to be managed and attended to. The user insight through this questionnaire identifies the subjective success given by the respondents to the presentation, functionality, and overall security of the secure chat server.

5.4 Testing

The testing for the completed C# Chat Server cannot rely on unit tests to provide an adequate result, as such manual testing is required to be taken place to cover all general user requirements, edge cases, and to purposefully attempt to break the sever. From the questionnaire results, 2 security flaws are already known, this being a susceptibility to denial of service attacks and decompiling. The following table will outline the test, expected results, and actual results with provided appendix reference as evidence.

5.4.1 Server Side Testing

Test being run	Input values	Expected Results	Appendix Reference
Incorrect login: Wrong username Correct password	String value "IncorrectUsername" Password "AdminTest!@12"	Takes both username and password. Will then notify the user logging in that there is an incorrect password or email address	9.2.1.1
Incorrect login: Correct username Wrong password	String values Username: AdminTest Password: WPassword!@12	Takes both username and password. Will then notify the user logging in that there is an incorrect password or email address	9.2.1.2
Incorrect password format	String values Username: AdminTest Password: Password	For a notice to arrive saying that there is an incorrect format	9.2.1.3
Correct login	String values: Username: AdminTest Password: AdminTest!@12	Opens the main menu for the server, with the admin's name stated at the top of the screen	9.2.1.4
Starting the server	Menu option 1	For the last action committed tag to change to "Server started", and clients to begin to connect	9.2.1.5

Attempting to start the server with an instance running	Menu option 1	For the last action committed to change to “Server Started” Last error should change to “Attempted to deploy a server with another server instance running “	9.2.1.6
Attempting to close a server with an instance running	Menu option 2	For the last action committed to change to “Server killer “ Last error shouldn’t change	9.2.1.7
Attempting to close a server with no instance running	Menu option 2	The last error status should update to state “Attempted to stop a server with no server instance running”	9.2.1.8
Adding a new admin	Menu option 3 Name: Jessica Username: JessicaTest Password: JessicaF!@12	The server should accept the name, username, and password. Changing the last action to “Admin Added”. The MongoDB should also contain the new account details and the password should be hashed.	9.2.1.9
Removing an admin	Menu option 4 Choose to remove the JessicaTest account option 2	Choosing menu 4 should open up a list of indexed admin accounts. Choosing the admin account for JessicaTest should update the last committed to “ Admin Deleted “ and the account should be removed from the MongoDB	9.2.1.10
Removing a user	Menu option 5 Choosing the option to remove <u>Jess@test.com</u>	Choosing menu 5 should bring up an indexed list of user email addresses saved on the database. Selecting the index for <u>Jess@test.com</u> , should delete the correct record in MongoDB and update the last action to “User Deleted”	9.2.1.11
View ALL logs, ERROR logs, INFO logs, FATAL logs	Menu option 6 Choose the most recent log date option Choose each option for the different output types	Choosing menu option 6 should display the list of log file names in descending date order. Selecting a date should present multiple options relating to which log codes to review. Going through each log code option should just display logs relating to that logging code	9.2.1.12

Figure 35 – Server Side Test Case Table

5.4.2 Client Side Testing

Test being run	Input values	Expected Results	Appendix Reference
Connecting to the server whilst it's running	Opening client exe	For the login/registration window to open	9.2.2.1

Connecting to the server while the server is not running	Opening client exe	Error message notifying that there is a connection error.	9.2.2.2
Correctly registering an account	Email JessicaTest@test.com Username Jessica Password UserTest!@12	Entering the relevant details and pressing register should bring up a message box saying “Account Added “ and the MongoDB server should be updated with the new account. The password should appear to be hashed and an account salt added.	9.2.2.3
Incorrect email or password format	Email IncorrectFormat.com Username Jessica Password Incorrectformat	An error pop up should appear notifying the user that there is an incorrect format	9.2.2.4
Duplicate email account	Email JessicaTest@test.com Username Jessica Password UserTest!@12	A message box should appear notifying the user that there is a duplicate account	9.2.2.5
Correctly logging in	Email JessicaTest@test.com Username Jessica Password UserTest!@12	A message box should appear saying the user has correctly logged in. The user will then be presented with the GUI for the chat client. The title of the page will change to reflect the client's username	9.2.2.6
Incorrect email address	Email JessicaTest@false.com Password UserTest!@12	An error notification should appear next to the email address box identifying that no matching email address could be found	9.2.2.7
Incorrect password	Email JessicaTest@test.com Password PIncorrect!@12	An error notification should appear next to the password entry notifying that there was an issue with the password.	9.2.2.8
Attempting to login into an account that is already logged in	Logging into the same account twice Email JessicaTest@false.com Password UserTest!@12	The first account can log in but the second account will trigger an error notifying that this account may already be logged in or there is an issue with the password	9.2.2.9
Logging out by the logout button	Pressing logout	Will take the user back to the main menu	9.2.2.10

Exiting the application by the close X	Pressing the close X	Will disconnect the client from the server, the server will log a message saying the client has disconnected	9.2.2.11
The server closes whilst a client is connected	Press menu option 2 on the server menu as admin	A message box will appear saying the server has stopped and the program will close	9.2.2.12
Sending messages on the chat server	Have 2 clients connected and send messages	Messages sent between clients will appear on all machines	9.2.2.13

Figure 36 - Client-Side Test Case Table

6 Critical Evaluation

6.1 Results Interpretation

The questionnaires used to analyse the subject opinion of the users who participated in the survey on topic areas relating to the appearance and functionality of the secure chat server indicated that all the vital components of the chat server operated as intended and that the appearance of the chat server was appreciated and approved by all respondents. Issues related to the security of the chat server are not necessarily fundamental flaws with the overall security with review and additional research into the raised security concerns required and potential fixes implemented.

Testing of both the server and chat client proved that all functionality worked as intended with evidence being provided in the appendix; these tests included checks into the effect of adding accounts and their appearance on the MongoDB with these tests concluding that all passwords are successfully hashed and salted. Being able to log into these accounts provided evidence that the authentication process implemented in this project works successfully. Finally, tests involving separate client's communication via the server are evidence that the AES encryption between client and server is working as expected even with multiple clients connected.

6.2 Limitations of results

The tests and surveys performed for the critical evaluation of this project covered vital questions and use cases, however, the testing methodology lacked more severe and stress tests. More advanced testing such as penetration testing or stress testing to the total capacity of the server's ability could yield results that would better help further development of advances to this project.

6.3 Project Deliverables

This project set out clearly defined core objects that must be completed for project completion. As well as core requirements for features that any implementations must contain and desirable features that the final project could contain if time restrictions allow.

6.3.1 Objective 1

The first objective set out in this project was the research into various attack vectors that chat servers and other servers face regularly alongside the mitigations required for these vectors. The research for this object discovered the attack vectors and mitigation of man in the middle

attacks and account hijacking. The vectors discovered in this objective fed into the following objectives to guide research.

6.3.2 Objective 2

This objective focused on the research of encryption methodologies; throughout this objective, both asymmetric and symmetric encryption were spoken about, with a primary focus on RSA and AES encryption. Additionally, in this stage, the precursor for the key exchange system is discussed in terms of how asymmetric encryption is used to securely transmit symmetric keys. This research was used to aid development in the implementation stage and used in object 3 for further research.

6.3.3 Objective 3

Objective 3 had the focus of research secure technologies, protocols, and other processes used for secure development. During this objective various topics were discussed that were later implemented into the project, these included the authorisation system, hashing, and the input validation. Additionally, technologies such as SSL and Log4Net were decided to be implemented into the project. Finally, the persistent storage mechanism of using a remote MongoDB database was also discussed and decided in this objective.

6.3.4 Objective 4

The fourth objective set out the task of implementing the research from the previous 3 objectives into a single coherent project, this covered a solution both for the server and the client. The client was built with the ability to handle the encryption handshake and to send messages securely to the server using AES encryption. While the server has the primary task of handling client connections, login attempts, registrations, message collection and delivery, AES encryption, RSA handshakes, and database management.

6.3.4 Implementation requirements

On top of the core project objective, there were additional project deliverables categorised into 2 sections, required and desired. All requirements discussed in the required sections were implemented into the final development, and one of the desired outcomes was completed in this development this being the persistent MongoDB storage.

6.4 Critical Evaluation Conclusion

The feasibility of researching and implementing a secure chat server using C# and industry standard technology can be considered a success with the metrics provided in the results gathered. Both the survey and testing data indicate that the implementation of a secure chat server both yielded a subject approval with appearance and functionality and a technical approval with passings all tests presented.

While the research performed into the various attack vectors, technologies, and utilities required to make a secure chat server proved successful the assistance in developing a product that can defend against man in the middle attacks (SSL), data confidentiality (Encryption), persistent password management (MongoDB and hashing), all while providing smooth user interaction with a clear warning, errors, and extensive admin controls on the server-side. Additional research topic areas should have been researched such as ways to mitigate decompiling and ways for better message transfer such as an end to end encryption rather than client-server encryption. Such additional research areas would have yielded a more secure product that is capable to defend against a great number of attack vectors.

Additionally, the defined objectives were satisfied with each area being appropriately discussed and developed upon. All the required objectives were completed, however, there is sufficient room for further improvements as only one of the desired outcomes was developed. These desired outcomes were not developed into the finalised project due to time and development restrictions; however, the developed project has been programmed in a way that allows for flexibility for future addition without the requirement to completely refactor the entire project.

7 Conclusion and future work

7.1 Conclusion

This project aimed and determined the feasibility of researching and creating a secure chat server using C# and industry standard technologies and techniques to best mitigate the cyber threat of malicious actors from interfering with the integrity, confidentiality, and authenticity of messages being communicated between the server and connected clients.

This project has succeeded with research into these areas subsequently being used for the development of both a server-side and client-side application that allows for secure communication and mitigates against the threats investigated in the research and falls in line with guidance given by significant bodies such as the American National Institute of Standards and Technology and Microsoft. Through surveys and testing the project operated as intended, allowing for secure messaging and an easy-to-use experience, however, some security flaws were identified at these stages, ones that were not initially investigated during the research stage.

7.2 Future Improvements and Work

As discussed in the results and critical evaluation, there are already defined additions and features that can be implemented into future work for this development. This is a rework of the client interface to sufficiently allow for anchoring of the interface and to allow for multiple chat forums to run and be interacted with concurrently without the need to connect to a new server. Additionally, improvements to the client interface would be a more energetic colour scheme and allow the functionality of secure photo and video transmission.

Future improvement work is not only limited to the client-side but also the security of the entire project; additional research and development would be required to investigate and mitigate against not only the identified security flaws discovered in the results sections but also to investigate any other potential attack vectors that require to be more sufficiently addressed. Additionally, the message transmission system in any future development should be adopted to allow for an end-to-end encryption methodology instead of a client-server methodology, this would prevent anyone except the people communicating to know what was being said.

Finally, quality-of-life improvements should be researched and implemented in any future development of this project. With implementations to allow for users to disable or delete their accounts without needing to contact the admins of the server to do so and allowing for users to use the enter key to send messages. Additionally, to implement functionality that would allow admins to remotely connect to the server for management rather than purely relying on local access for server management.

9 Appendix

9.1 Ethics Form

SECTION A: Project Definition

FOR UNDERGRADUATE & TAUGHT POSTGRADUATE ONLY

Complete the following table with full and relevant information relating to your research.

Student Name	Jessica Clara Fealy
Student Number	18024092
Student E-mail Address (please use University e-mail)	18024092@students.southwales.ac.uk
Name of Principal Project Supervisor	Simon Payne
Project Title	C# Secure Chat Server

<p>Briefly describe the project, being sure to identify any aspects that are relevant to the Ethical Evaluation in Section B.</p> <p>NOTE: A project determined to be High Risk will need to include additional information in Section B to fully-specify the risks and mitigations.</p>	<p>To research, design, and developed a C# chat server using secure programming principles that utilises industry standard libraries, encryption methodologies, and other pre-existing technologies.</p>
<p>Please add an explanation of your study in plain English, with particular focus on any parts of your study which involve human participants. No more than 100 words. This is to help the Faculty Research Ethics Committee (FREC) to understand the project.</p>	<p>Creating a chat server. Questionnaire friends, family, and fellow students about the functionality of the security and features of the chat server. Questionnaire people in industry.</p>

SECTION B: Ethical Evaluation FOR UNDERGRADUATE & TAUGHT POSTGRADUATE ONLY

Consider the following points to determine the level of ethical risk your research presents:

1. Involves those who are considered vulnerable such as:
 - Children under 16.
 - Adults with learning difficulties.

Unless in an accredited setting, accompanied by a carer or professional with a duty of care.
2. Involves those who are considered highly vulnerable such as:
 - Adults or children with diagnosed mental illness/terminal illness/dementia/in a residential care home.
 - Adults or children in emergency situations.
 - Adults or children with limited capacity to consent
3. Involves those who are “dependent” on others (such as teacher or lecturer to student). Unless in an accredited setting associated with normal working conditions or routines and within normal operating hours, such as a cultural institution, pre-school, school, or youth club where the research is carried out as part of professional practice such as curriculum development.
4. Requires full NHS ethical approval via the Integrated Research Application System.
5. Requires a Human Tissue Act license.

6. Involves “covert” procedures as in covert observation studies.
7. Involves anything considered “sensitive”. For example, does not carry a risk of those involved disclosing information which compromises the research (e.g., illegal activities; activities where moral opinion may differ, potential professional misconduct – work errors).
8. Induces significant psychological stress or anxiety or produce humiliation or cause more than fleeting harm / negative consequences beyond the risks encountered in the normal life of the participants (and where the potential for fleeting “harm” is clearly detailed in the participant information sheet). If in doubt regarding definition of the above terminology, please contact the research governance office.
9. Involves administration of drugs, placebos, or other substances (such as food substances or vitamins) as part of this study.
10. Involves invasive procedures (not limited to blood sampling, collection of biological samples, or passing current through a participant’s body, etc.).
11. Offers any financial inducements to participate in the study.
12. Intends to recruit serving prisoners or serving young offenders via Her Majesty’s Prison & Probation Service.

For your course, there may be specific requirements in **addition** to these, depending on the nature of the subject and how your project is assessed. You must also complete those requirements.

If **none** of the 12 points above apply, then the research can be considered **Low Risk**, *unless your course identifies additional criteria relevant to your subject that would render it High Risk*. This Section is then signed off by yourself and your supervisor and held on file for review by FREC.

If **any** of the 12 points applies, then the research is considered **High Risk** and students must bring the matter to the attention of their research supervisor immediately. **Research cannot then commence until mitigations for the risk are agreed by FREC**. Seek advice from your supervisor, who can help you identify mitigations of the risk or redesign as a Low Risk project.

All students must complete the section below, in collaboration with their supervisor.

Please strike through the statement that **does not** apply.

1. An ethics review has been completed, and the project has been identified as Low Risk.
- ~~2. An ethics review has been completed, and a High Risk was identified. I agree to explain how they may be mitigated below and agree to abide by any conditions identified at this stage, by my Project Supervisor, the School or the Faculty. I understand that High Risk projects can only proceed with approval from the Faculty Research Ethics Committee.~~

Issues: (Include as much information as possible to help FREC members to understand the issues. Extend onto additional pages as necessary.)

Proposed mitigations: (Include as much information as possible to help FREC members to understand the mitigations. Extend onto additional pages as necessary.)

Student's Signature: Jessica Clara Fealy
Date: 19/10/2021

Supervisor's statement: I have ensured due diligence and accountable decision making by the student. I have sought appropriate advice where required to support my judgment in this.

Supervisor's Signature: Simon Payne
Date: 19/10/2021

Any false or mis-represented information contributing to this Ethical Evaluation, including attempting to pass off a High Risk project as a Low Risk project, is subject to the Student Misconduct Regulations and may also have legal repercussions.

Both signatures are required for all projects, both Low Risk and High Risk.

9.2.2 Client

9.2.2.1

The screenshot shows a window titled "Chat Client" with standard Windows window controls (minimize, maximize, close). Inside the window, there are two panels: "Login Controls" and "Registration Controls".

Login Controls:

- Email:
- Password:
- Login:

Registration Controls:

- Username:
- Email:
- Password:
- Register:

9.2.2.2

The screenshot shows a message box with a close button (X) in the top right corner. The text inside the box reads:

Server is currently not running!
Please wait for server to start

At the bottom of the message box is an "OK" button.
